

## Original Studies

# Radiation Dose Benchmarks in Pediatric Cardiac Catheterization: A Prospective Multi-Center C3PO-QI Study

Priscila C. Cevallos,<sup>1</sup> BS, Aimee K. Armstrong,<sup>2</sup> MD, Andrew C. Glatz,<sup>3</sup> MD MSCE, Bryan H. Goldstein,<sup>4</sup> MD, Todd M. Gudauskas,<sup>5</sup> MD, Ryan A. Leahy,<sup>6</sup> MD MS, Christopher J. Petit,<sup>7</sup> MD, Shabana Shahanavaz,<sup>8</sup> MD, Sara M. Trucco,<sup>9</sup> MD, and Lisa J. Bergersen,<sup>1\*</sup> MD MPH

**Objectives:** This study sought to update benchmark values to use a quality measure prospectively. **Background:** Congenital Cardiac Catheterization Outcomes Project – Quality Improvement (C3PO-QI), a multi-center registry, defined initial radiation dose benchmarks retrospectively across common interventional procedures. These data facilitated a dose metric endorsed by the American College of Cardiology in 2014. **Methods:** Data was collected prospectively by 9 C3PO-QI institutions with complete case capture between 1/1/2014 and 6/30/2015. Radiation was measured in total air kerma (mGy), dose area product (DAP) ( $\mu\text{Gy}\cdot\text{M}^2$ ), DAP per body weight, and fluoroscopy time (min), and reported by age group as median, 75<sup>th</sup> and 95<sup>th</sup> percentile for the following six interventional procedures: (1) atrial septal defect closure; (2) aortic valvuloplasty; (3) treatment of coarctation of the aorta; (4) patent ductus arteriosus closure; (5) pulmonary valvuloplasty; and (6) transcatheter pulmonary valve implantation. **Results:** The study was comprised of 1,680 unique cases meeting inclusion criteria. Radiation doses were lowest for pulmonary valvuloplasty (age <1 yrs, median mGy: 59, DAP: 249) and highest in transcatheter pulmonary valve implantation (age >15 yrs, median mGy: 1835, DAP: 17990). DAP/kg standardized outcome measures across weights within an age group and procedure type significantly more than DAP alone. Radiation doses decreased for all procedures compared to those reported previously by both median and median weight-based percentile curves. These differences in radiation exposure were observed without changes in median fluoroscopy time. **Conclusions:** This study updates previously established benchmarks to reflect QI efforts over time.

## INTRODUCTION

Catheterization procedures are increasingly utilized to treat pediatric congenital heart disease, necessarily exposing children to radiation [1–5]. The risk of radiation exposure in children is of particular concern compared to the adult population, as children are more vulnerable to direct tissue damage and induced biochemical damage [3,6–8]. Further, as life expectancy in children with congenital heart disease increases, often from the interventional procedures themselves, these children may be subject to repeated catheterizations, resulting in higher cumulative radiation exposure over their lifetimes [9,10]. As a result of increased awareness and publication on radiation exposure in children with congenital heart disease, many pediatric catheterization labs have begun to participate in radiation reduction initiatives, such as implementing local radiation safety protocols, as well as collaborating in national and international radiation reduction quality improvement (QI) efforts [9,11–17]. However, there is a paucity of published radiation dose metrics for reference and comparison among pediatric cardiac catheterization procedures.

The American College of Cardiology (ACC) Quality Metrics Working Group endorsed a QI radiation dose metric defined as the proportion of cases receiving radiation doses not exceeding the 95<sup>th</sup> percentile of a predefined dataset [18]. Ghelani et al. established initial radiation dose benchmarks with data from the Congenital Cardiac Catheterization Project on Outcomes – Quality Improvement (C3PO-QI), a multi-institutional registry which aims to reduce radiation doses at participating sites [13]. These benchmarks were established retrospectively with data obtained from 2009 to 2013 to allow application of the quality metric and to assess the impact of C3PO-QI's radiation reduction initiative. This initiative included 2,713 cases among 7 participating centers. However, benchmarks should be adjusted periodically to account for broad reductions in radiation dose and to revise improvement expectations. This study sought to prospectively update the previously retrospectively established benchmarks with contemporary data to reflect the collaborative's outcomes since 2014. Importantly, the current study not only includes a larger number of participating centers, but also comes after institution of radiation reduction efforts in all participating centers, thus reflecting improving, lower radiation exposures.

## METHODS

Prospective data collection began among C3PO-QI participating institutions on January 1, 2014 for all cases including interventional catheterization procedures classified into six procedural types: (1) atrial septal defect (ASD) closure; (2) aortic valvuloplasty (AV); (3) treatment of coarctation of the aorta (COA); (4) patent ductus arteriosus (PDA); (5) pulmonary valvuloplasty (PV); and (6) transcatheter pulmonary valve (TPV) implantation. These procedures were selected for this analysis to best represent a homogeneous case mix and to facilitate comparison based on previously reported measures [13]. Out of the 15 participating institutions, 9 centers contributed complete institutional case entry in the C3PO-QI database during this study period required for inclusion in this dataset analysis. All data from the remaining centers were excluded due to incomplete case capture during the study period. IRB approval was obtained for this study at each participating site in accordance with institutional requirements. All cases performed between January 1, 2014 and June 30, 2015 were screened for eligibility. Interventional procedures involving more than one procedure were excluded to maintain case type homogeneity and generalizable interpretation of the radiation outcome among these isolated procedure types.

Radiation doses were analyzed as the sum of biplane imaging for the following variables: (1) total air kerma (mGy), a predictor of deterministic effects, estimates the radiation exposure at the interventional reference point, (2) dose area product (DAP,  $\mu\text{Gy} \cdot \text{M}^2$ ), an indicator of the risk of stochastic effects, represents the products of radiation dose and exposed area (also known as kerma area product,  $P_{KA}$ ), (3) DAP per body weight ( $\mu\text{Gy} \cdot \text{M}^2/\text{kg}$ ) a surrogate for energy delivered indexed by body weight, and (4) total fluoroscopy time (min).

## Statistical Summary

Radiation dose outcomes were reported as median, 75<sup>th</sup> percentile, and 95<sup>th</sup> percentile with corresponding 95% confidence interval, stratified by case type and age group (<1 yr of age, 1–4 yrs of age, 5–9 yrs of age, 10–15 yrs of age and >15 yrs of age). To determine the relationship between radiation exposure and body weight, as previously reported in other studies,

Values in parenthesis are 95% confidence intervals for the reported value. ASD = atrial septal defect; AV = aortic valvuloplasty; COA = coarctation of the aorta; PDA = patent ductus arteriosus; PV = pulmonary valvuloplasty; TPV = transcatheter pulmonary valve.

DAP per body weight was further stratified by body weight group according to the following categories: <10 kg, 10–20 kg, 20–30 kg, 30–50 kg, and >50 kg [10,13,16]. Case types, age groups, and body weight categories with insufficient data, arbitrarily chosen to be less than 10 representative cases, were excluded in the summary tables. To determine the relationship between age, weight, and DAP and DAP/kg, a scatter

plot was created for TPV placement in patients > 15 yrs to compare trend lines between median DAP and DAP/kg. Linear regression lines were fitted for DAP and DAP/kg by weight, and the slopes of these lines were compared using standardized regression coefficients. Additionally, smoothened weight-based percentile curves for total air kerma and DAP were generated by procedure type (ASD, AV, PDA, PV) using quantile

Values in parenthesis are 95% confidence intervals for the reported value. ASD = atrial septal defect; AV = aortic valvuloplasty; COA = coarctation of the aorta; PDA = patent ductus arteriosus; PV = pulmonary valvuloplasty; TPV = transcatheter pulmonary valve.

regression to estimate the 50<sup>th</sup>, 75<sup>th</sup> and 95<sup>th</sup> percentiles. Curves for COA and TPV procedures were not included as these procedures are most commonly performed within a certain age group (48% of COA treatments occur in patients <1 yrs, 62% of TPV placements occur in patients >15 yrs).

This current study's data was further compared to the procedure-specific radiation benchmarks reported by Ghelani et al. in 2014. DAP radiation doses obtained from Ghelani et al. were converted to  $\mu\text{Gy}\cdot\text{M}^2$  from  $\text{Gy}\cdot\text{cm}^2$  to facilitate comparisons. To identify changes since the establishment of the initial radiation dose benchmarks, comparison weight-based percentile curves for median total air kerma and DAP for the two cohorts were performed by including interaction terms of weight by study cohort in the quantile regression models. The C3PO-QI quality metric was applied to the contemporary cohort using the benchmark values established by Ghelani et al. The quality metric equals the number of observed cases not exceeding the benchmark percentile value divided by

the total cases in the procedure and age group. The metric was applied to all procedure type age groups with the largest volume by percentile (%) of cases not exceeding the Ghelani et al. benchmarks. Statistical significance was defined as  $P < 0.05$ .

## RESULTS

A total of 1680 unique cases, among 8707 cases entered for the nine sites in the registry between January 1, 2014 and June 30, 2015 were included and ranged from 75 to 301 cases per site (median, 214 cases). The distribution of interventional cases is shown in Table I. While all three radiation dose variables, total air kerma, DAP and fluoroscopy time, were collected for nearly all cases, data for one of the three variables were not available in a small number of cases (missing: total air kerma,  $n = 50$ ; DAP,  $n = 55$ ; fluoroscopy time,  $n = 197$ ). Among the analyzed procedures, the lowest radiation doses were noted in PDA closure and PV, with a median total air kerma of 73

95 <sup>th</sup> percentile	–	–	673 (422, 673)	559 (422, 954)	812 (583, 1418)

Values in parenthesis are 95% confidence intervals for the reported value. ASD = atrial septal defect; AV = aortic valvuloplasty; COA = coarctation of the aorta; PDA = patent ductus arteriosus; PV = pulmonary valvuloplasty; TPV = transcatheter pulmonary valve.

and 69 mGy, DAP of 407 and 326  $\mu\text{Gy}\cdot\text{M}^2$ , and DAP/kg of 37 and 53  $\mu\text{Gy}\cdot\text{M}^2/\text{kg}$ , respectively. As seen in Table I, fluoroscopy time did not correlate with radiation exposures. For example, while radiation exposures varied widely between ASD and PV procedures for total air kerma, DAP, and DAP/kg, similar total fluoroscopy times were recorded for both procedure types.

Age-based stratification is presented in Tables (II–V) for age groups including more than 10 cases. As ASD and TPV cases among younger patients and PV procedures among older patients are not commonly performed, data for these procedure types were not included due to small case volume. Age-stratified radiation doses for PDA closure were lowest in children less than 4 yrs of age for total air kerma (median 58 mGy) and lowest in <1 yrs and 1–4 yrs for DAP (median 323  $\mu\text{Gy}\cdot\text{M}^2$  and 355  $\mu\text{Gy}\cdot\text{M}^2$  respectively). However, when using a weight based correction factor, the lowest exposure outcome was in the larger 5–9 yr olds for DAP/kg (median 27  $\mu\text{Gy}\cdot\text{M}^2/\text{kg}$ ). The lowest exposure for PV procedures was seen in the highest volume age group <1 yr old for total air kerma and

DAP (median 59 mGy, 249  $\mu\text{Gy}\cdot\text{M}^2$ ). However, again, when a weight based corrected outcome was applied, 1–4 yrs had lowest exposure for DAP/kg (median 33  $\mu\text{Gy}\cdot\text{M}^2/\text{kg}$ ). Among the procedures reported, TPV placement had the highest exposures for any age group but was predominantly performed in patients >15 yrs of age. TPV placement had the highest median total air kerma, DAP and DAP/kg values at 1450 mGy, 13551  $\mu\text{Gy}\cdot\text{M}^2$  and 257  $\mu\text{Gy}\cdot\text{M}^2/\text{kg}$ , respectively. Age-stratified TPV placement radiation doses were highest in >15 yrs for total air kerma, DAP and DAP/kg (median 1835 mGy, 17990  $\mu\text{Gy}\cdot\text{M}^2$  and 271  $\mu\text{Gy}\cdot\text{M}^2/\text{kg}$ ).

DAP/kg by body weight category is presented in Table VI. Median radiation doses are comparable to those seen across DAP/kg by age group presented in Table IV. Among COA cases, for example, radiation doses varied similarly across body weight categories (median 79, 99, 97, 83, 129 DAP/kg across increasing weight groups) and age group (median 79, 95, 93, 98, 140 DAP/kg across increasing age groups). The scatterplot depicting linear trend lines by median DAP and DAP/kg for TPV placements in patients >15 yrs is

95 <sup>th</sup> percentile	–	–	119 (57, 119)	110 (85, 119)	121 (97, 145)

Values in parenthesis are 95% confidence intervals for the reported value. ASD = atrial septal defect; AV = aortic valvuloplasty; COA = coarctation of the aorta; PDA = patent ductus arteriosus; PV = pulmonary valvuloplasty; TPV = transcatheter pulmonary valve.

seen in Fig. 1. DAP/kg (standardized coefficient, 0.47) shows a significant decrease in slope when graphed across weight compared to that of DAP (standardized coefficient, 0.21). In this age group, the slope of the curve for DAP/kg is less than that of DAP alone as an outcome measure when the outcomes are assessed across weights. This suggests that DAP indexed to weight may provide better standardization of the outcome measure which might allow more equitable comparison of dose in populations with different weight cohorts.

Radiation dose outcomes and previously established benchmarks as published by Ghelani et al. for this collaborative are shown in Table VII. For all procedure types, the median total air kerma and DAP radiation dose were lower ( $P < 0.001$ ) (Table VII). TPV placement showed the greatest difference (median decreased by 836 mGy and 9449  $\mu\text{Gy} \cdot \text{M}^2$ ). The lowest exposure procedures, AV, PDA closure, and PV, exhibited the smallest change in median radiation doses. The decreases in total air kerma and DAP seen across all

procedure types were observed without changes in median fluoroscopy time across all procedure types, except for TPV where the time decreased significantly ( $P = 0.002$ ) in the contemporary cohort.

The weight-based percentile curves showing radiation doses for total air kerma and DAP are shown in Fig. 2 and 3. As seen in Fig. 2, the current study indicates a parabolic relationship between the radiation dose variables, total air kerma and DAP, and weight. This relationship is similarly seen in the previously published Ghelani et al. data, however, there is a significant decrease in radiation doses for total air kerma and DAP across all procedure types ( $P < 0.001$ ) in the contemporary cohort (Fig. 3).

Application of the C3PO-QI quality metric to the contemporary cohort shows age specific, procedure type radiation doses for both total air kerma and DAP meeting quality metric goals (Tables IX and VIII). The highest percentage not exceeding the 75<sup>th</sup> percentile quality metric was seen in ASD closures in patients 1–4 yrs for total air kerma (90%), and PDA closures in

1–4 yrs and PV in < 1 yr for DAP (92%). The highest percentage not exceeding the 95<sup>th</sup> percentile quality metric was seen in PV in patients < 1 yrs for total air

kerma (98%), and treatment of COA and PV in patients < 1 yr for DAP (100%). The procedure type with the lowest percentage not exceeding the 75<sup>th</sup> and 95<sup>th</sup> percentile quality metric for total air kerma was seen in AV in patients < 1 yrs (78% and 89%, respectively). For DAP, the lowest percentage not exceeding the 75<sup>th</sup> percentile was seen in AV in patients < 1 yrs (85%), and the lowest percentage not exceeding the 95<sup>th</sup> percentile was seen in ASD closures in patients 1–4 yrs (98%).

## DISCUSSION

This is the first multi-center report to update previously established benchmark values to allow for calculation of a novel radiation dose exposure metric proposed by the ACC Quality Metric Working Group using prospectively collected contemporary data by the C3PO-QI collaborative. In our recent experience, radiation doses for total air kerma and DAP decreased across all procedure types. These decreases were seen with little observed changes in median fluoroscopy

time, except for a significant decrease fluoroscopy time for TPV placements. Since this reduction in fluoroscopy time in TPV procedures occurred without a change in median weight over time (59.6 kg, Ghelani, et al.; 59.0 kg, Contemporary Cohort;  $P = 0.75$ ), it is likely attributed to increased operator experience and shorter procedure times in the contemporary cohort. This lack of decrease in median fluoroscopy time indicates that clinicians still use fluoroscopy as needed for catheter manipulations and likely reduced radiation dose by reducing frame rates, using “store fluoro” instead of cine, and good collimation. Hence, we continue to recommend the use of DAP and total air kerma, but not fluoroscopy time, as measures of radiation exposure. Additionally, our findings support the use of procedure-specific benchmarks for radiation dose variables across both age groups and body weight as a necessary standardizing adjustment in metric reporting. These contemporary benchmarks, including the application of the quality metric, are being used to quantify improvements in C3PO-QI’s ongoing quality improvement efforts.

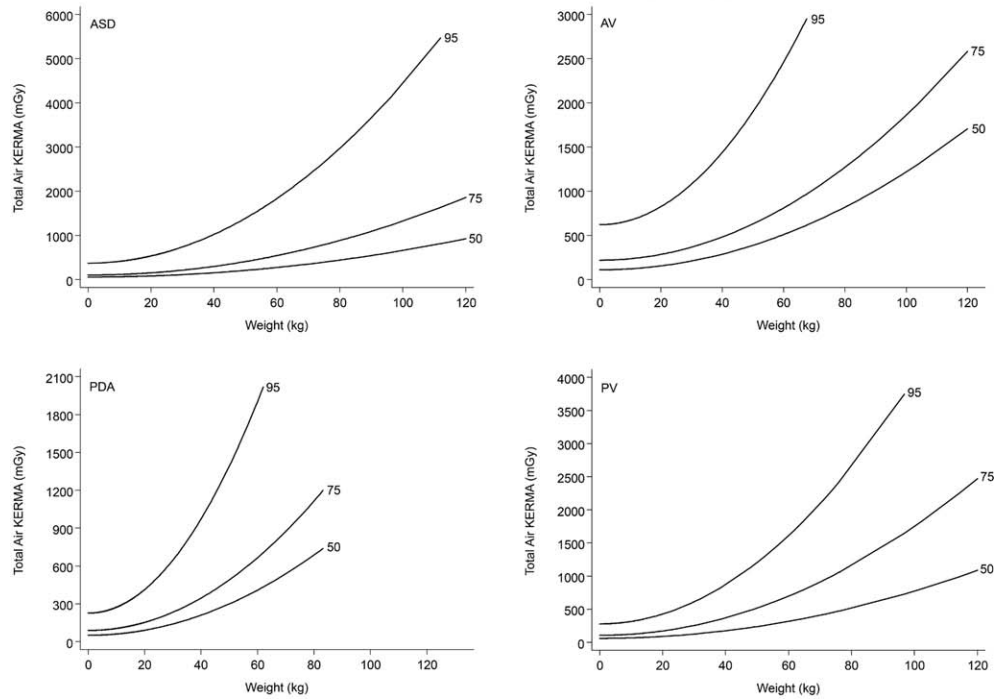

The decreases in radiation dose seen in these new benchmarks occurred as participating centers formalized QI in their radiation dose reduction efforts. Examples of such initiatives include increased radiation safety awareness in the catheterization lab, inter-institutional sharing of practices and operator techniques among participating sites in C3PO-QI, online reporting tools allowing for tracking of radiation doses longitudinally, and identification of procedural specific areas requiring improvement using new reporting programs such as Tableau<sup>TM</sup> (Tableau Software, Seattle, Washington). Importantly, some participants have noted that the radiation dose data immediately available for review via the C3PO-QI website enables and empowers physicians to further reduce radiation dose [16]. Additionally, installation of new catheterization laboratory equipment and utilization of radiation reporting software have made it easier for operators to

make modifications to radiation settings (e.g. frame rate, pulse rate) and receive notifications of patient radiation exposures throughout the case. Installation of next generation catheterization laboratory equipment may further result in substantial radiation dose reduction without necessitating changes in exposure settings or resulting in loss of image quality [19]. Efforts to minimize radiation exposure as low as reasonably achievable (the ALARA principle) while maintaining “optimization” of imaging protocols have driven advances and refinement of operator techniques to ensure ongoing decreases in radiation exposure [19–24]. The impact of these ongoing improvements on radiation dose reduction, as demonstrated in this study, suggests that benchmarks should be periodically revised to reflect broad reductions in radiation doses [11,19,21]. Importantly, while efforts to reduce radiation should be maximized, the ability to perform interventional procedures safely and effectively should not be compromised.

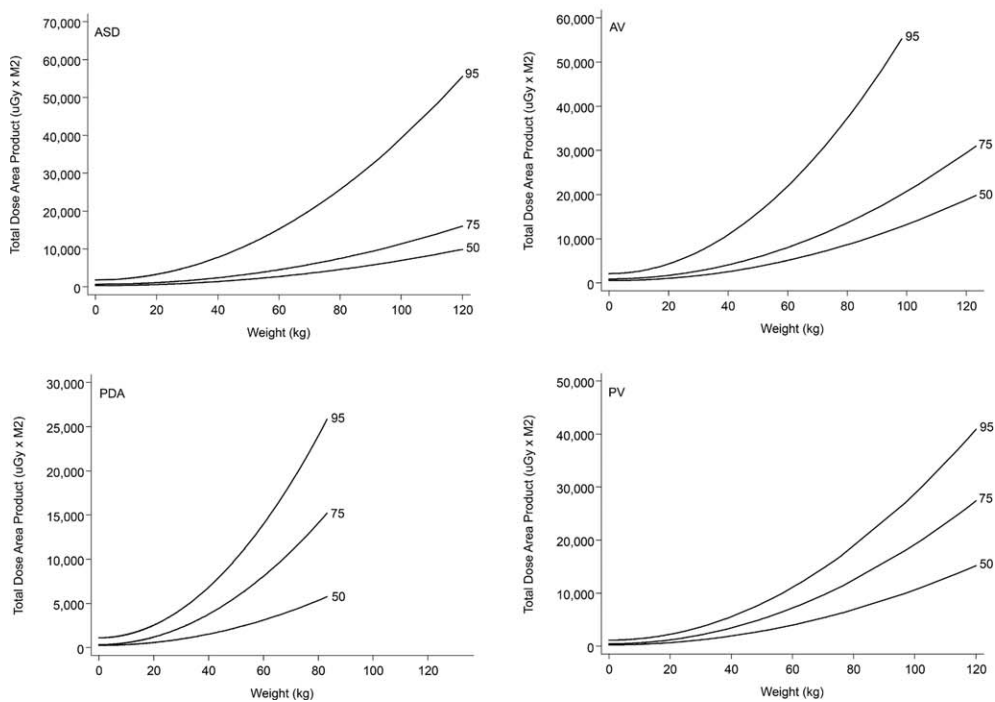

The present study included a DAP/kg analysis by age group and body weight category to allow comparisons with recent literature [11,14,21,25]. Our study found median DAP/kg values for ASD closure and PV lower than those reported by Kobayashi et al. (34 and 53 DAP/kg, 40.9 and 55.5 DAP/kg, respectively). However, the DAP/kg doses presented in this study for AV and TPV placement were higher than those published by Kobayashi et al. The Kobayashi et al. analysis was not stratified by body weight categories or age groups and thus do not allow for direct comparison or necessary adjustment based on the age and weight distribution in the two populations. Differences among participating sites in age of equipment, equipment manufacturer, operator techniques, patient population, case mix distribution and complexity of procedure type are major contributors to the differences in radiation doses reported by other studies. While these new radiation dose benchmarks may be higher in comparison to

population by weight distribution. The significant decrease in slope for DAP/kg indicates that it is a better outcome metric for population comparisons than DAP alone within an age group to account for differences in distribution of weights in similar age and case type populations being compared for radiation exposure. Thus, DAP/kg may have value as a metric for longitudinal assessment of radiation exposure for QI reduction efforts, not as a direct measure for evaluating or comparing stochastic risk.

The present study is not without limitations. While this study attempts to update radiation dose benchmarks since the study by Ghelani et al., the present study includes two additional sites overall, and, therefore, exact comparisons do not account for baseline radiation dose measures from the newer cohort of hospitals. This report, limited by individual site numbers, does not explore variation of equipment age and type, individual site outcomes or identification of best practices, as the data are summarized by the median for the group. Additionally, as the benchmarks provided reflect longitudinal averages obtained from a large cohort, radiation exposure comparisons are more suitable when conducted with aggregate data as opposed to an individual procedure. Lastly, as the cohort of hospitals present in this study differs greatly in size of hospital, number of procedures performed and case type distribution, the results of this study may be skewed by the procedures and practices of the larger centers.

## CONCLUSION

This prospective multi-center study updates previously established procedure-specific radiation dose values to reflect QI efforts over time. Across all interventional procedure types explored, we observed a decrease in radiation exposure across all ages. This difference in radiation exposure was seen at C3PO-QI participating institutions incentivized to reduce radiation and as QI initiatives were formalized at participating centers. These contemporary thresholds can be applied in quality measurement and comparative assessment at institutions performing cardiac catheterization procedures for congenital heart disease.
